9 **ABSTRACT**

10 In order to understand the climate dynamics of the Mesozoic greenhouse world, it is vital to
11 determine paleotemperatures from higher latitudes. For the Jurassic and Cretaceous climate, there
12 are significant discrepancies between different proxies and between proxy data and climate models.
13 We determined paleotemperatures from Late Jurassic and Early Cretaceous belemnites using the
14 carbonate clumped isotope paleothermometer and compared these values to temperatures derived
15 from TEX₈₆ and other proxies. From our analyses, we infer an average temperature of ca. 25 °C for
16 the upper part of the water column of the Southern Atlantic Ocean. Our data imply that for mid to
17 high latitudes, climate models underestimate marine temperatures by >5 °C and, therefore, the
18 amount of warming that would accompany an increase in atmospheric CO₂ of more than 4x pre-
19 industrial levels, as is projected for the near future.

20 **INTRODUCTION**

21 Modern anthropogenic CO₂ production has resulted in rapid climate change, with near-
22 surface air temperatures in the high latitude regions rising at ca. twice the global average rate
23 (Screen and Simmonds, 2010). Predictions of how global and polar temperatures will change over

the next few decades in response to continued CO₂ release may be improved by studying past climate response to elevated CO₂ levels. The Late Jurassic to Early Cretaceous (164 to 100 million years ago) was characterized by extremely high but variable levels of atmospheric CO₂ (from ca. 2x to 8x pre-industrial levels; Wang et al., 2014; Foster et al., 2017), yet reconstructions of marine temperatures, particularly for the high latitudes, are contradictory (e.g., Huber et al., 1995; Price and Gröcke, 2002; Bice et al., 2003; Poulsen, 2004; Jenkyns et al., 2012; Price and Passey, 2013; O'Brien et al., 2017).

The stable oxygen isotope composition of the carbonate remains of marine organisms is the most extensively used temperature proxy, yet high-latitude sea-surface temperatures (SST) derived from independent organic geochemical paleothermometers, i.e., TEX₈₆, may be ca. 10 °C warmer than δ¹⁸O-based temperature reconstructions (e.g., Mutterlose et al., 2010; O'Brien et al., 2012) and up to 6 °C warmer than general circulation model (GCM) predictions (Price and Passey, 2013). These differences have led some authors to suggest that the high TEX₈₆ SST estimates are too warm (Hollis et al., 2009; Meyer et al., 2018), and there is an ongoing debate as to which calibration is appropriate for applications of the TEX₈₆ proxy at specific regions and different intervals of the geologic record (Kim et al., 2012; Taylor et al., 2013). Conversely, δ¹⁸O-based paleotemperature reconstructions rely on several assumptions, among which is the oxygen isotope composition of the seawater (δ¹⁸O_{sw}; Huber et al., 1995; Price and Gröcke, 2002; Bice et al., 2003), and the accuracy of these assumptions still needs to be verified. If the interpretation of warm sub-polar paleo-ocean temperatures can be confirmed, they imply that past and future polar warming may be much greater (i.e., >5 °C) than indicated by climate models. Furthermore, such warm temperatures test the veracity of claims of Early to mid-Cretaceous polar ice, in particular from those studies deriving data from locations distal to the poles (Miller, 2009).

Deep Sea Drilling Project Site 511, on the Falkland Plateau (51°00.28'S, 46°58.30'W), is particularly well suited for studying Jurassic and Cretaceous climate due to its abundant, exceptionally preserved macrofossils, including belemnites (Jeletzky, 1983; Price and Sellwood, 1997; Price and Gröcke, 2002). The Falkland Plateau was located at approximately 53 °S during the Late Jurassic–Early Cretaceous (Scotese, 2014; Fig. 1). Mean annual temperatures derived from GCMs for the Late Jurassic and Early Cretaceous indicate that the temperatures of the Falkland Plateau region (avg. 10–22 °C) are representative of similar southern hemisphere paleolatitudes (Lunt et al., 2016). Earlier research at Site 511 used the TEX₈₆^H paleotemperature proxy to suggest that warm sea-surface conditions (26–35 °C) existed during the Late Jurassic–Early Cretaceous interval (Jenkyns et al., 2012). These paleotemperatures are consistently warmer than paleotemperature estimates based on $\delta^{18}\text{O}_{\text{belemnite}}$, assuming a $\delta^{18}\text{O}_{\text{sw}}$ of -1‰ SMOW (11–21 °C; Price and Gröcke, 2002). Another study, undertaken on Barremian to Aptian sediments from two outcrops in northern Germany, also shows that $\delta^{18}\text{O}_{\text{belemnite}}$ -derived paleotemperatures (12–16 °C) are consistently cooler than TEX₈₆-based estimates (26–32 °C; Mutterlose et al., 2010). Jenkyns et al. (2012) argue that the offset is due to TEX₈₆ recording sea surface temperatures, whereas belemnites record temperatures from deeper water, possibly from below the thermocline.

In this study, we apply the carbonate clumped isotope paleothermometer to exceptionally well-preserved belemnite rostra from Site 511. This proxy provides seawater temperature estimates independent of $\delta^{18}\text{O}_{\text{sw}}$ (Price and Passey, 2013; Wierzbowski et al., 2018). In addition to constraining high latitude temperatures, we set out to resolve the uncertainties associated with previous $\delta^{18}\text{O}$ -based belemnite temperature reconstructions.

MATERIALS AND METHODS

Stratigraphy and samples

70 The lithology of the sampled section of Site 511 consists of grey-black, thinly laminated
71 mudstones and soft, grey claystones, which were deposited in a periodically anoxic, low-energy,
72 shallow (< 400 m) basin (Basov and Krasheninnikov, 1983; Jeletzky, 1983).

73 A geothermal gradient of 7.4 °C/100 m has been determined (Langseth and Ludwig, 1983)
74 at Site 511, thus, for the samples analyzed in this study, we can estimate a maximum burial
75 temperature of ca. 50 °C. At elevated temperatures, diffusion of carbon and oxygen isotopes in the
76 carbonate mineral lattice may reset the initial bond-ordering (e.g., Henkes et al., 2014). However,
77 theoretical calculations based on laboratory experiments provide evidence that solid-state diffusion,
78 even in wet and high-pressure conditions, is insignificant below 100 °C burial temperatures on a
79 timescale of 100–160 Ma (Passey and Henkes, 2012). Thus, it is unlikely that the belemnite rostra
80 analyzed in this study were affected by solid-state reordering.

81 Eleven belemnites (*Belemnopsis* sp.) were selected for maximum stratigraphic coverage and
82 were geochemically screened to include the best-preserved samples, as indicated by available trace
83 element concentrations (i.e., low Fe and Mn; high Sr and Mg concentrations; Price and Gröcke,
84 2002; [Supplemental Information](#)) and cathodoluminescence analyses (Figure 5 of Price and
85 Sellwood, 1997). Subsamples were derived avoiding the margins and apical zone, as these areas are
86 much more susceptible to diagenetic overgrowth and cementation, respectively than the rest of the
87 belemnite (e.g., Ullmann et al., 2015). In addition, we made electron backscatter diffraction (EBSD)
88 analyses and secondary electron microscopy (SEM-BSE) images of selected rostra at the Goethe
89 University Frankfurt ([Supplemental Information](#)).

90 **Clumped Isotope Analyses**

91 Carbonate digestion (90 °C), CO₂ purification (cryotrap and GC) and subsequent
92 measurement procedures (ThermoFisher MAT 253) are identical to the techniques described in
93 Wierzbowski et al. (2018). Raw isotope values were calculated using the IUPAC isotopic

parameters, and are projected to the CO₂ reference frame ($\Delta_{47}^{(RFAC)}$; Petersen et al., 2019). To verify the consistency and precision of the clumped isotope measurements, six carbonate standards (ETH1–4, MuStd, Carrara) were analyzed along the samples (Data S1). We used the in-house Wacker et al. (2014) calibration to convert $\Delta_{47}^{(RFAC)}$ values to temperatures (Supplemental Information; Petersen et al. 2019). Temperature uncertainties are based on external 1SE (including *t*-value) that is always larger than or identical to the best attainable internal precision as represented by the shot noise limit (0.004–0.005‰).

RESULTS

Electron Microscopy

All investigated rostra, excluding the areas adjacent to the apical line and the surface, are made up of optical calcite and the c-axis of the calcite grains point radially outwards (Figs. S1-S4). The distribution of the crystallographic a-axes also follows a pattern. This is analogous to pristinely preserved rostra (Stevens et al., 2017). Our EBSD and SEM-BSE analyses suggest that recrystallization, which would change the original orientation of the biogenic calcite grains, did not occur in the sampled areas.

Clumped Isotope Analyses

The $\Delta_{47}^{(RFAC)}$ values range between 0.690(±0.011)‰ and 0.707(±0.015)‰. The 1SE uncertainty for the clumped isotope measurements, calculated from 4–6 replicate analyses are between 0.004‰ and 0.015‰ (mean 0.010‰). The $\Delta_{47}^{(RFAC)}$ values yield seawater temperatures ranging between 21 °C and 28 °C (mean 25 °C) and show no significant stratigraphic trend (Fig. 2). The average uncertainty for the reconstructed temperatures is ±4 °C. Steeper-sloped calibrations yield indistinguishable temperatures within ±1SE (Data S1).

DISCUSSION

117 The Δ_{47} -derived temperature range (21–28 °C, mean 25 °C) for the entire section is higher
118 than those temperatures reconstructed via stable oxygen isotope paleothermometry (11–19 °C,
119 mean 16 °C, assuming $\delta^{18}\text{O}_{\text{sw}} = -1\text{‰}$ SMOW; Price and Gröcke, 2002), and cooler, and rarely
120 within error, of SST estimates derived from TEX₈₆ (25–31 °C; Fig. 2; Jenkyns et al., 2012). In this
121 study, as in Jenkyns et al. (2012), we calculate TEX₈₆ temperatures using the TEX₈₆^H calibration
122 (Kim et al., 2010). Given the shallow-water and high latitude setting of Site 511 TEX₈₆^H may yield
123 maximum SST estimates (Schouten et al., 2013; Taylor et al., 2013). In contrast to TEX₈₆^H, the
124 linear calibration used of O'Brien et al. (2017) yield ca. 2–3 °C warmer temperatures, whereas the
125 calibrations that assume a non-surface export depth of GDGTs (Kim et al., 2012; Schouten et al.,
126 2013) yield ca. 5–6 °C cooler estimates (Fig. 2). Although the TEX₈₆^H proxy is likely the most
127 appropriate for a high latitude setting such as Site 511, there is ongoing discussion and revision of
128 the various calibrations, and ongoing debate as to which calibration should be applied (e.g., Ho et
129 al., 2014; Inglis et al., 2015). The difference between the TEX₈₆^H and the Δ_{47} -derived temperatures
130 for Site 511 may be partially resolved by considering a seasonal bias in either proxy. It has been
131 postulated that belemnites, as nektonic cephalopods, reflect mean annual temperatures (MAT; Price
132 and Sellwood, 1997; Mutterlose et al., 2010), while TEX₈₆ may indicate summer temperatures,
133 rather than MAT (Leider et al., 2010; Hollis et al., 2012). Nevertheless, our Δ_{47} temperatures
134 suggest that belemnites were calcifying their rostra in the upper part of the water column (<200 m
135 depth), and are broadly consistent with TEX₈₆-derived SSTs, given the uncertainties listed above.
136 Such an interpretation is in alignment with an assumed predator lifestyle in the photic zone for
137 belemnites (Klug et al., 2016).

138 All three records from Site 511 show less than 7 °C variability across the entire Late
139 Jurassic and Early Cretaceous interval, although the low sampling resolution means it is not
140 possible to derive more detailed information on Jurassic and Cretaceous climate evolution. These

141 data confirm warm Late Jurassic–Early Cretaceous high latitude ocean temperatures, possibly
142 precluding the likelihood of substantial land ice, and are consistent with estimated MATs from
143 fossil plant assemblages from the Antarctic Peninsula (Francis and Poole, 2002). The most likely
144 mechanism to account for such warmth observed at Site 511 is high atmospheric greenhouse gas
145 concentrations and high polar heat transport. The shallow meridional temperature gradients of the
146 past greenhouse climates pose a significant challenge to numerical climate models (Huber and
147 Caballero, 2011), in that increased greenhouse gases may yield warm Polar Regions, but also
148 overheat the Tropics. MATs for the Cretaceous derived from coupled ocean-atmosphere climate
149 models provide estimates for 53 °S ranging from 12 °C to 21 °C (Zhou et al., 2008; Donnadieu et
150 al., 2016). The higher of these estimates are generated with 2240 ppm $p\text{CO}_2$ (8 x pre-industrial
151 levels; Donnadieu et al., 2016). These atmospheric CO_2 concentrations typically exceed estimates
152 of Cretaceous $p\text{CO}_2$ derived from fossil leaf stomatal index measurements, isotope-based or
153 geochemical model estimates (Wang et al., 2014; Foster et al., 2017).

154 Furthermore, it is crucial to consider the magnitude of a non- CO_2 component of local
155 climate change, before proxies from a single site are interpreted in a global context (Lunt et al.,
156 2016). GCM output indicates warm conditions during the Cretaceous at Site 511 when compared to
157 the Eocene (Lunt et al., 2016), with almost invariable modeled global mean temperatures over the
158 same period, when $p\text{CO}_2$ is kept constant. This suggests that contributions from other processes
159 (e.g., paleogeography) may account for some of the observed warmth. Despite these findings and
160 those of others (Donnadieu et al., 2016), the role of paleogeography in regulating climate remains
161 less than clear.

162 Such warm temperatures at Site 511 challenge our understanding of how the ocean-
163 atmosphere system operated in the past (Poulsen, 2004) and may also have important implications
164 for the prediction of future climates as they imply we may be underestimating future climate change

165 in such regions (Spicer et al., 2008). Proposed mechanisms to increase the transfer of heat toward
166 the poles (Schmidt and Mysak, 1996), including sensible and latent heat transfer via the atmosphere
167 and heat transfer via the oceans (Hotinski and Toggweiler, 2003), are hence implied. As Site 511
168 was situated in a seaway open to the southwest (Fig. 1), increased heat transfer via warm ocean
169 currents can only be derived from the Pacific. Thus, other processes, including heat transfer via the
170 atmosphere, might also be important for this region.

171 These new warm Δ_{47} -derived temperature reconstructions also have implications for basin-
172 scale hydrologies. In conjunction with the $\delta^{18}\text{O}_{\text{belemnite}}$ data (Price and Sellwood, 1997; Price and
173 Gröcke, 2002), we can estimate $\delta^{18}\text{O}_{\text{sw}}$, assuming the temperature dependence of oxygen isotope
174 fractionation between belemnite calcite and seawater corresponds to Kim and O'Neil (1997). The
175 $\delta^{18}\text{O}$ -temperature equation of Kim and O'Neil (1997) indicates that $\delta^{18}\text{O}_{\text{sw}}$ may have averaged
176 $+1.0\text{‰}$ SMOW ($1SE = 0.7\text{‰}$; Fig. 2, Data S1), heavier than the global average for an ice-free world
177 (-1‰ SMOW; Shackleton and Kennett, 1975). This could suggest that the semi-enclosed basin in
178 which Site 511 was located was dominated by evaporation; alternatively, it is quite possible that the
179 Kim and O'Neil (1997) calcite equation is not applicable to belemnite calcite.

180 CONCLUSIONS

181 This proxy-to-proxy intercomparison reduces the uncertainty on temperature estimates for
182 the Mesozoic high southern latitudes. Our Δ_{47} -derived temperatures, although slightly cooler, are
183 consistent with the $\text{TEX}_{86}^{\text{H}}$ reconstructions for sea-surface temperatures. The new Δ_{47} data, in
184 conjunction with $\delta^{18}\text{O}_{\text{belemnite}}$ data imply local $\delta^{18}\text{O}_{\text{sw}}$ values of ca. $1.0(\pm 0.7)\text{‰}$ SMOW, indicating a
185 strong role of evaporation on the Falkland Plateau, which was a semi-enclosed basin during the Late
186 Jurassic and Early Cretaceous. The warm reconstructed paleotemperatures, if extrapolated
187 poleward, reinforce evidence of temperate polar conditions and lack of polar ice. If these warm
188 ocean temperatures, occurring when $p\text{CO}_2$ in Earth's atmosphere were also high, prove accurate,

189 they may indicate that greenhouse gases could have heated the oceans during the Jurassic and
190 Cretaceous more than currently accepted. This suggests that future warming from elevated
191 atmospheric CO₂ concentrations may be much greater than that predicted by models.

339 **FIGURE CAPTIONS**

340 **Figure 1.** Paleogeographic setting of the Deep Sea Drilling Project Site 511. Early Cretaceous
341 paleogeographic reconstruction after Scotese (2014).

Figure 2. Jurassic and Early Cretaceous temperatures and seawater $\delta^{18}\text{O}$ from DSDP Site 511. **(A)** Clumped isotope seawater temperature reconstructions for Site 511 (this study) are compared to those based on $\delta^{18}\text{O}_{\text{belemnite}}$ (Price and Gröcke, 2002; Price and Sellwood, 1997; plotted using Kim and O’Neil, 1997, with an assumed $\delta^{18}\text{O}_{\text{sw}}$ of -1‰ SMOW) and TEX_{86} (Jenkyns et al., 2012). Infilled green circles represent $\delta^{18}\text{O}_{\text{belemnite}}$ temperatures from Price and Gröcke (2002), hollow green circles are the belemnites that were also used for clumped isotopes analysis in this study. For TEX_{86} temperatures, dotted lines used $\text{TEX}_{86}^{\text{H},0-200}$ (Kim et al. 2012., eq. 2), dashed used $\text{TEX}_{86}\text{-linear}$ (O’Brien et al., 2017, eq. 4), and solid line and points used the $\text{TEX}_{86}^{\text{H}}$ calibration (Kim et al. 2010, eq.10). **(B)** Reconstructed $\delta^{18}\text{O}_{\text{sw}}$ values (this study) using the equation of Kim and O’Neil (1997). Error bars represent for $\delta^{18}\text{O}_{\text{belemnite}}$ and Δ_{47} the 1SE of multiple replicate analyses; for $\text{TEX}_{86}^{\text{H}}$ the calibration error; and for $\delta^{18}\text{O}_{\text{sw}}$ the 1SE. corresponding to the Δ_{47} measurements. Age model construction is described in the [Supplemental Information](#), whereas data for this figure can be found in [Data S1](#).
