Background: Purchasing pigs from a positive farm may be an important risk factor for acquisition of MRSA CC398 in the recipient farms (Broens et al., 2010).

Objective: to provide conclusive molecular evidence that MRSA CC398 is transmitted vertically through the pig production chain by trade of MRSA-positive animals. Our hypothesis was that PFGE profiles found in the recipient farms would also be present in the corresponding supplying farms.

Methods: Six chains (group of farms related to each other by trade of animals) were included in the retrospective study (Chains F, G, P, I, Q, R). Two farms were included the prospective study (Farm 1 and Farm 2) where newly purchased gilts were sampled before entering the farm. Pools of samples from inside the farms and samples from these farms from 2009 were also included (Farm isolates). MRSA isolates from farms linked by commercial trade of pigs were typed using the PFGE protocol by Bosch et al., 2010, a highly discriminatory method allowing differentiation between different lineages of MRSA CC398 (van Wamel et al., 2010). GelCompar II software was used for the cluster analysis and *spa* types were assigned following the protocol by Harmsen et al., 2003. The study was structured in two parts: a retrospective study (isolates from the study by Broens et al., 2010) and a prospective study (isolates from Denmark).

Results: The results of the retrospective study and the prospective study are presented in Figures 1 and 2, respectively. In most but not all cases, MRSA transmission by trade was supported by PFGE analysis.

CONCLUSIONS

- MRSA CC398 strains can be transmitted through pig trading, which is important for the development of intervention strategies (Chains F, P, Q, R and Farm 2).
- Alternative transmission pathways may exist (there are identical strains among farms not related by trade, for example Chains Q and R).
- Association between PFGE profiles and *spa* types was not consistent (Figure 1).
